Template; Container

Learning Objectives:

Understand what is a template and why it is useful.

Understand what is a container, why a container of pointers is useful, what is a polymorphic container.

Know how to implement templated containers, containers of pointers and polymorphic containers.

Outline

- Templates
- Container of Pointers
- Polymorphic Container

Containers

Introduction

- Things like `IntSet` and `IntList` are often called **containers** or **container classes**.

- Their purpose in life is to "**contain**" other objects, and they generally have no intrinsic meaning on their own.

- **Question**: how can we write a `CharList`?
  - **Answer**: we have to write almost **exactly** the same code, changing each instance of `int` to `char`.

Containers

Introduction

- IntList versus CharList

```
struct node {
    node *next;
    int    v;
};

class IntList {
    node *first;
  public:
    void insert(int v);
    int remove();
    ...
};
```

```
struct node {
    node *next;
    char   v;
};

class CharList {
    node *first;
  public:
    void insert(char v);
    char remove();
    ...
};
```

Containers

Polymorphism

- It turns out we need to write the code **only once**, and can reuse it for each different type we want to use it for.

- Reusing code for **different types** is called **polymorphism** or **polymorphic** code:
  - "poly" meaning "many" and "morph" meaning "forms".

- One way to achieve polymorphism in C++ is **templated containers**.

Containers

- Often, any **single** container needs to contain only **one type** of object.

- If this is the case, then you can use a C++ mechanism called "**templates**" to write the container code only once.

- You can then use that single implementation to realize any container of any **single** type.

Containers

Templating

- Consider the following fragments defining a **list-of-int** and a **list-of-char**:

```cpp
struct node {
    node *next;
    int    v;
};

class List {
    node *first;
  public:
    void insert(int v);
    int remove();
    ...
};
```

```cpp
struct node {
    node *next;
    char   v;
};

class List {
    node *first;
  public:
    void insert(char v);
    char remove();
    ...
};
```

Containers

Templating

- It's like someone took the list-of-int definition and **replaced** each instance of `int` with an instance of `char`.
- Templates are a mechanism to do exactly that.

```cpp
struct node {
    node *next;
    int    v;
};

class List {
    node *first;
 public:
    void insert(int v);
    int remove();
    ...
};
```

```cpp
struct node {
    node *next;
    char   v;
};

class List {
    node *first;
 public:
    void insert(char v);
    char remove();
    ...
};
```

Containers

Templates

- The intuition behind templates is that they are code with the "**type name**" left as a **(compile-time) parameter**.

- So, they are another form of **parametric generalization** except this time, the **parameter is a type**, not a variable.

- To start, you first need to declare that something will be a template:

```
template <class T>
class List {
  ...
};
```

T stands for "the name of the type contained by this List".

By convention, we always use T for the name of the "type" over which the template is parameterized.

Containers

Templates

- The intuition behind templates is that they are code with the "**type name**" left as a **(compile-time) parameter**.

- So, they are another form of **parametric generalization** except this time, the **parameter is a type**, not a variable.

- To start, you first need to declare that something will be a template:

```
template <class T>
class List {
    ...
};
```

C++ uses "class" to mean "type" here, but that doesn't mean only class names can serve as "T". Any valid type such as int and double can.

Containers

Templates

```
template <class T>
class List {
 public:
  bool isEmpty();
  void insert(T v);
  T remove();

  List();
  List(const List &l);
  List &operator=(const List &l);
  ~List();

 private:
  ...
};
```

Now, you write the definition of the List, using T where you mean "the type of thing held in the list".

Note: For this example, we put the public part first, and the private part after

Containers

Templates

```cpp
template <class T>
class List {
 public:
  bool isEmpty();
  void insert(T v);
  T remove();

  List();
  List(const List &l);
  List &operator=(const List &l);
  ~List();

 private:
  ...
};
```

Note: The only thing different between this definition and the `IntList` one is that we've used T rather than `int` to name objects held in this list.

This will work for any type.

Containers

- We also have to pick a representation for the node contained by this List, and that representation must also be parameterized by T.
  - The "node" type has to have an element of type T.

- We do this by creating a **private** type, which is part of this class definition:

```
private:
 struct node {
   node *next;
   T      v;
 };
```

Containers

Templates

```
template <class T>
class List {
 public:
  // methods

  // constructors/destructor

 private:
  struct node {
    node *next;
    T      v;
  };
  ...
};
```

So, this type "node" is only available to implementations of this class' methods.

On the other hand, this node will hold only objects of the appropriate type.

Containers

Templates

```cpp
template <class T>
class List {
 public:
   // methods/constructors/destructor
 private:
   struct node {
      node *next;
      T      v;
   };
   node *first;
   void removeAll();
   void copyList (node* np);
};
```

The rest of the class definition is just what you expect

Containers

Templates

- All that is left is to define each of the method bodies.
- Each **method** must also be declared as a "**templated**" method and we do that in much the same way as we do for the class definition.
- Each function begins with the "template declaration":

  template <class T>

- And each method name must be put in the "List<T>" namespace:

```
template <class T>
void List<T>::isEmpty() {
   return (first == NULL);
}
```

Containers

Templates

- `isEmpty()` isn't that interesting, since it doesn't use any T's.
- Here is a more interesting one:

```
template <class T>
void List<T>::insert(T v) {
    node *np = new node;
    np->next = first;
    np->v = v;
    first = np;
}
```

- The argument, `v`, is of type T which is exactly the same type as `np->v`.

When list.insert(v) is called, how many times value v is copied?

Select the correct answer.

- **A.** 0.
- **B.** 1.
- **C.** 2.
- **D.** It depends on the compiler.

Containers

- The `#include` and compiling of templates are a little bit different.

- You should put your class member function definition also in the .h file, following class definition. So, there is no .cpp for member functions

```
template <class T>
class List {
  ...
};
template <class T>
void List<T>::insert(T v) {
  ...
}
```

list.h

Containers

Templates

- The function header of the constructor is
  ```
  List<T>::List()
  List<T>::List(const List<T> &l)
  ```

Must have <T>! No <T>! Have <T>!

- The function header of the destructor is
  ```
  List<T>::~List()
  ```

Must have <T>! No <T>!

- The function header of the assignment operator is
  ```
  List<T> &List<T>::operator=(const List<T>
  &l)
  ```

Must have <T>! Have <T>!

20

Containers

Templates

- To use templates, you specify the type T when creating the container object.

```
// Create a static list of integers
List<int> li;
// Create a dynamic list of integers
List<int> *lip = new List<int>;
// Create a dynamic list of doubles.
List<double> *ldp = new List<double>;
```

- Thereafter, you just use these normally.

Outline

- Templates
- Container of Pointers
- Polymorphic Container

Container of Pointers

Introduction

- So far, we've inserted and removed elements **by value**.

- In other words, we **copy** the things we insert into/remove from the container.

- Copying elements by value is fine for types with "small" representations.

  - For example, all of the built-in types.

- This is **not** true for "large" types – any nontrivial struct or class would be expensive to pass by value, because you'll spend a lot of your time copying.

Container of Pointers

Introduction

- **<u>Question</u>**: suppose we had a list of `BigThings`. When you call `insert()`, how many copy-related operations will be done?

- Answer: Twice
  - First time as an argument to `insert()`, and
  - Second time when you store the item in the list node.

```
foo.insert(A_Big_Thing);

void List::insert(BigThing v) {
  node *np = new node;
  np->value = v;
  np->next = first;
  first = np;
}
```

This is unacceptable!

Container of Pointers

Introduction

- Instead of copying large types by value, we usually insert and remove them **by reference**.
  - The container stores **pointers-to-BigThing** instead.

    ```
    struct node {
      node *next;
      BigThing *value;
    };
    ```

- So, if we have a `BigThing` list, its `insert` and `remove` methods have the following type signatures.

    ```
    void insert(BigThing *v);

    BigThing *remove();
    ```

Container of Pointers

Introduction

```cpp
struct node {
  node *next;
  BigThing *value;
};

void ListBigThing::insert(BigThing *v) {
  node *np = new node;
  np->next = first;
  np->value = v;
  first = np;
}
```

Templated Container of Pointers

Practice: when we define templated container of pointers, we do **NOT**
- define a template on **object**
- and define
  List<BigThing *> ls;

```
template <class T>
class List {
  public:
    ...
    void insert(T v);
    T       remove();
  private:
    struct node {
        node *next;
        T       o;
    };
    ....
};
```

Templated Container of Pointers

Instead, we

- define a template on **pointer**
- and define
  List<BigThing> ls;

```
template <class T>
class List {
  public:
    ...
    void insert(T *v);
    T     *remove();
  private:
    struct node {
        node *next;
        T     *o;
    };
    ....
};
```

Container of Pointers

Templates

- Containers-of-pointers are subject to two broad classes of potential bugs:
  1. Using an object after it has been deleted
  2. Leaving an object **orphaned** by **never** deleting it
Container of Pointers

Use

- To avoid the bugs related to container of pointers, one usual "pattern" of using container of pointers has an **invariant**, plus three **rules** of use:

  - **At-most-once invariant**: any object can be linked to at most one container at any time through pointer.

 1. **Existence**: An object must be **dynamically allocated** before a pointer to it is inserted.

  2. **Ownership**: Once a pointer to an object is inserted, that object becomes the property of the container. No one else may use or modify it in any way.

  3. **Conservation**: When a pointer is removed from a container, either the pointer must be inserted into **some** container, or its referent must be **deleted**.

At-most-once Invariant

- Any object can be linked to at most one container at any time through pointer.

Violate the invariant!
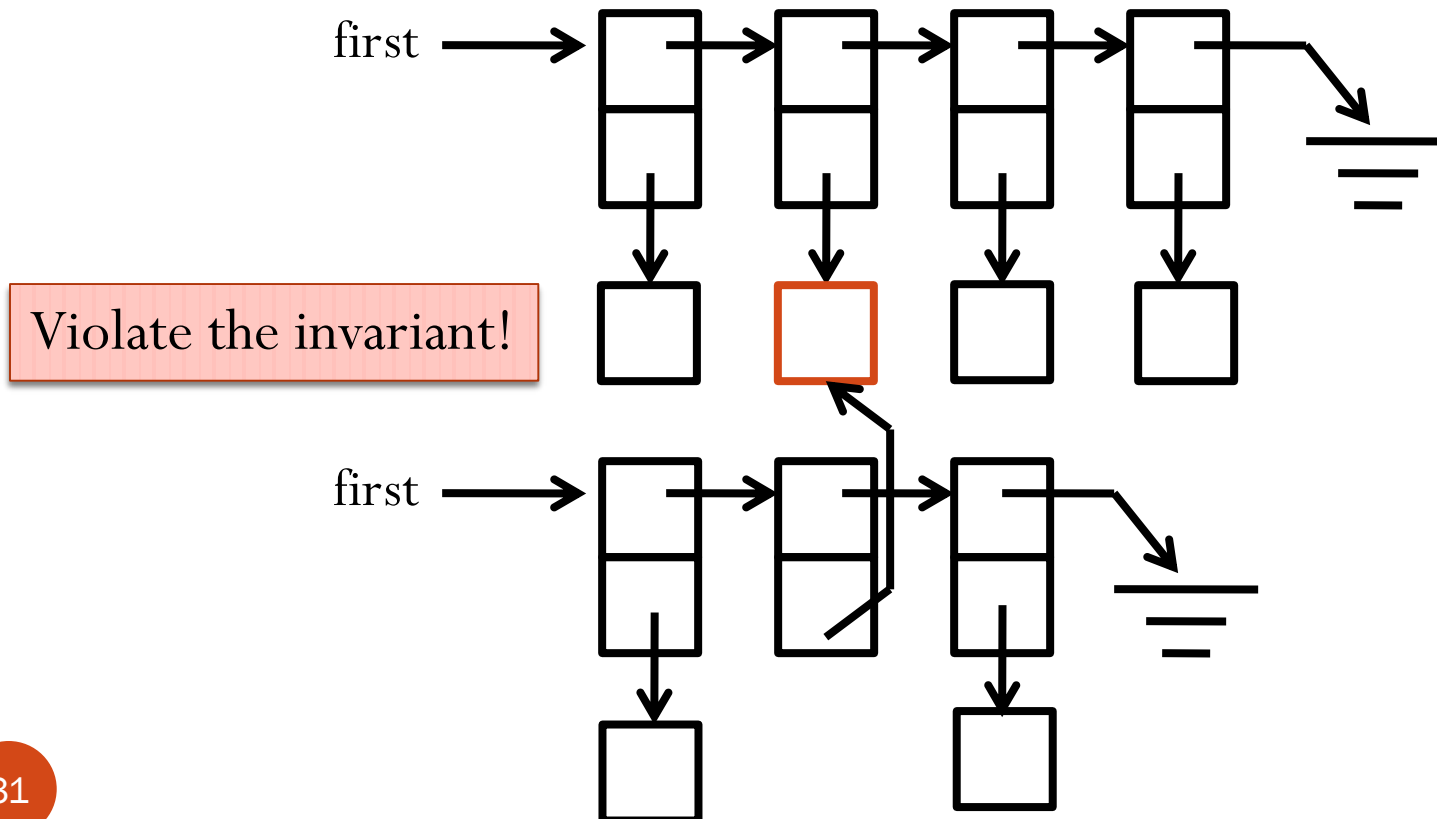

Existence Rule

- An object must be **dynamically allocated** before a pointer to it is inserted

```
List<BigThing> l;
// l: container of pointer
BigThing b;
l.insert(&b); ✗

List<BigThing> l;
// l: container of pointer
BigThing *pb = new BigThing;
l.insert(pb); ✓
```

Ownership Rule

- Once a pointer to an object is inserted, that object becomes the property of the container. No one else may use or modify it in any way.
Conservation Rule

- When a pointer is removed from a container, either the pointer must be inserted into **some** container, or its referent must be **deleted**.
- Either be inserted into another container
- Or delete the object

Container of Pointers

Templates

- These three rules have an important implication for any method that **destroys** an existing container.
  - When a container is destroyed, the objects contained in the container should also be deleted!

- There are (at least) two such methods that could destroy a container:
  1. **The destructor**: Destroys an existing instance.
  2. **The assignment operator**: Destroys an existing instance before copying the contents of another instance.

Which rule is violated?

Consider the following implementation of the destructor for a singly-linked list, using the interface we've discussed so far:

```
template <class T>
List<T>::~List() {
  while (!isEmpty()) {
    remove();
  }
}
```
```
struct node {
  node *next;
  T* value;
};
```

int *

```
template <class T>
T* List<T>::remove() {
  node *victim = first;
  if(isEmpty()) {
    listIsEmpty e;
    throw e;
  }
  T* result = victim->value;
  first = victim->next;
  delete victim;
  return result;
}
```

Select **the** correct answer.

- **A.** At-most-once invariant.
- **C.** Ownership.

B. Existence.

D. Conservation.

# Containers

Destructor

- To fix this, we **must** handle the objects we remove:

```
template <class T>
List<T>::~List() {
  while (!isEmpty()) {
    T *op = remove();
    delete op;
  }
}
```
This keeps conservation rule.
Container of Pointers

Copy

- Copy is also tricky for container of pointers.

- Here is the original singly-linked list of $T*s$:

Does it violate any invariant or rules?

orig ⟶ first ⟶ ...

- Here is the old copy constructor and utility function:

```
template <class T>
List<T>::List(const List &l) {
  first = NULL;
  copyList(l.first);
}
```

```
template <class T>
void List<T>::copyList(node *list) {
  if(!list) return;
  copyList(list->next);
  insert(list->value);
}                          T * type
```
Select **the** correct answer.

- **A.** At-most-once invariant.　　　**B.** Existence.
- **C.** Ownership.　　　　　　　　　**D.** Conservation.

Container of Pointers

Copy

- The list we would end up with is:

This violates the at-most-once invariant
Container of Pointers

Copy

- Now, if we remove the first item of the `new` list, we delete the first node, and return a pointer to the item.

- The client will use the item and delete it (Why?).

- Leaving us with this:

orig

first

**dangling
pointer!**

new

first

Container of Pointers

Copy

- Clearly, this is not a good thing because we aren't doing a "full" **deep copy**.

- The list nodes are deeply copied, but the Ts are not since we are copying the pointers, but **not** the objects they point to.

Container of Pointers

Copy

- Fix:

```
template <class T>
void List<T>::copyList(node *list) {
    if (!list) return;
    copyList(list->next);
    T *o = new T(*list->value);
    insert(o);
}
```
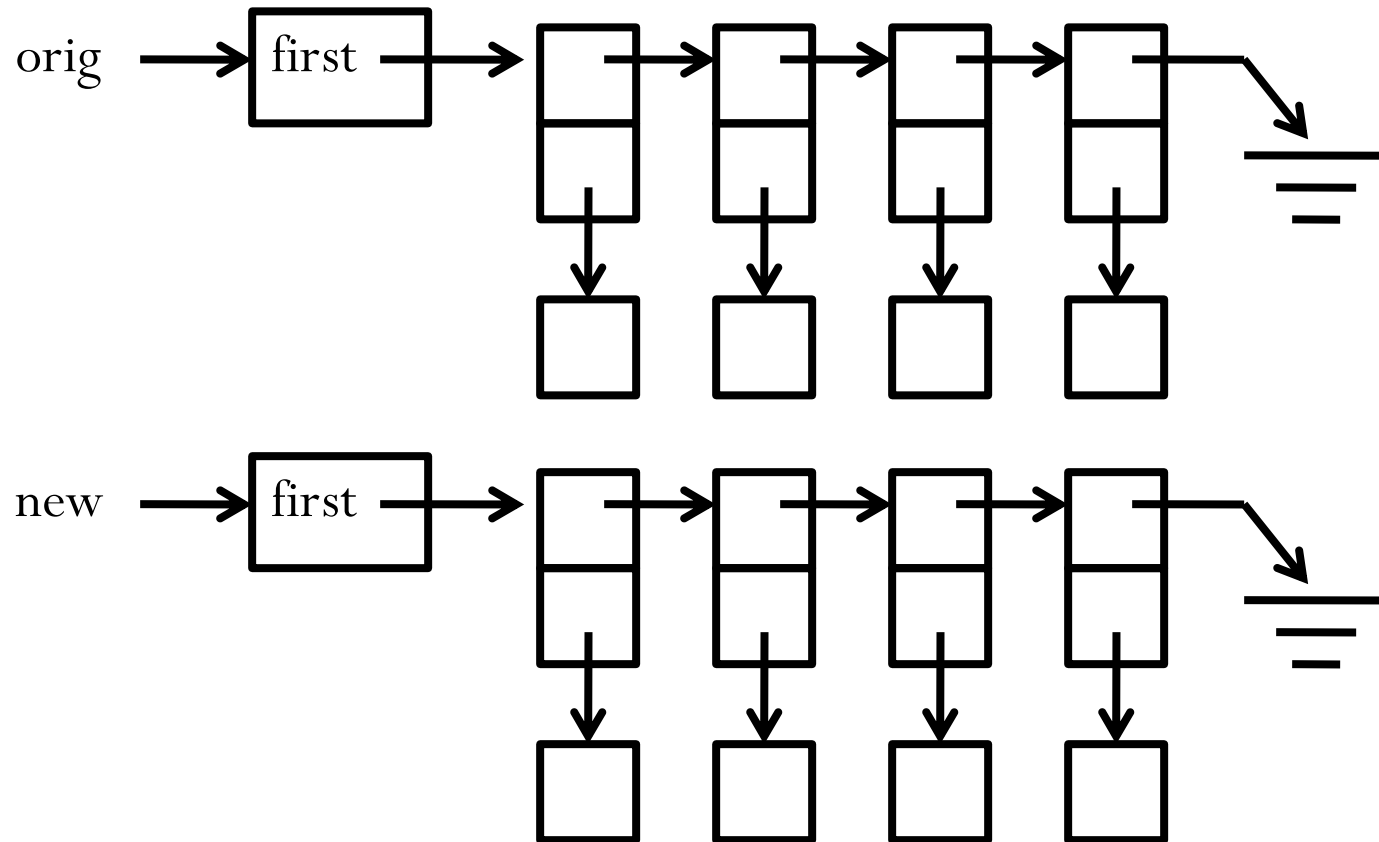

-> binds tighter than *

What does the blue statement mean?

Container of Pointers

Copy

- The list we would end up with is:

deep copy!

Templated Container of Pointers

- Given container of pointers, the `List` template **must know** whether it is something that holds `T`'s or "pointers to `T`".

- The former **cannot** delete the values it holds, while the latter **must** do so.

- So, if we want to write a template class that holds pointer-to-T, we should provide a version based on pointer.

Containers

Templates

```
template <class T>
class PtrList {
  public:
    ...
    void insert(T *v);
    T    *remove();
  private:
    struct node {
        node *next;
        node *prev;
        T    *o;
    };
    ....
};
```

```
template <class T>
class ValList {
  public:
    ...
    void insert(T v);
    T    remove();
  private:
    struct node {
        node *next;
        node *prev;
        T    o;
    };
    ....
};
```

Containers

Templates

- This means that if we create two lists of `BigThings`:

  ValList<BigThing> vbl;
  PtrList<BigThing> pbl;

- Then the first list takes `BigThings` by value:

  BigThing b;
  vbl.insert(b);

- But the second list takes them as pointers:

  BigThing *bp = new BigThing;
  pbl.insert(bp);

This technique is preferable if you expect most (or even some) of your `Lists` to hold `BigThings`.

Containers

Templates

- This means that if we create two lists of `BigThings`:

```
ValList<BigThing> vbl;
PtrList<BigThing> pbl;
```

- Then the first list takes `BigThings` by value:

```
BigThing b;
vbl.insert(b);
```

- But the second list takes them as pointers:

```
BigThing *bp = new BigThing;
pbl.insert(bp);
```

However, it is **impossible** to have only a **single** implementation of `List` that can correctly contain things either as pointer or by value.

Outline

- Templates
- Container of Pointers
- **Polymorphic Container**

Containers

Polymorphic containers

- Templates are checked at compile time, but when used straightforwardly, they cannot hold more than one kind of object at once, and sometimes this is desirable.

- There is another kind of container, called a "**polymorphic**" container, that **can** hold more than one type at once.

- The intuition behind polymorphic containers is that, because the container must contain **some** specific type, we'll manufacture a **special "contained" type**, and every real type will be a **subtype** of this contained type.

Containers

Polymorphic containers

- We are going to use derived class mechanism

```
class bar: public foo {
  ...
};
```

- <u>Recall</u>: a `bar*` can always be used where a `foo*` is expected, but not the other way around.
```
bar b;
foo *pf = &b;
```

Containers

Polymorphic containers

- We can take advantage of this by creating a "dummy class", called `Object`, that looks like this:

```
class Object {
 public:
   virtual ~Object() { }
};
```

- This defines a single class `Object` with a virtual destructor.

- Remember that if a method is virtual, it is also virtual in all derived classes.

- Why we need this? Because when a base-class pointer to a derived-class object is deleted (for example, in function **removeAll()**), it will call the destructor of the derived class.

Containers

Polymorphic containers

- Now, we can write a `List` that holds `Objects`:

```
struct node {
  node    *next;
  Object *value;
};
```

```
class Object {
 public:
  virtual ~Object() {};
};
```

```
class List {
  ...
 public:
  void    insert(Object *o);
  Object *remove();
  ...
};
```

Containers

Polymorphic containers

- To put `BigThings` in a `List`, you define the class so that it is derived from `Object`:

```
class BigThing : public Object {

...

};
```

- By the derived class rules, a `BigThing*` can always be used as an `Object*`, but not the other way around.

- So the following works without complaint:

```
BigThing *bp = new BigThing;
l.insert(bp); // Legal due to
              // substitution rule
```

Containers

Polymorphic containers

- However, the compiler complains about the following because `remove()` returns an `Object *`; we cannot use a base class pointer when a derived class pointer is expected:

```
BigThing *bp;
bp = l.remove();
```

- However, we can do this:

```
Object *op;
BigThing *bp;

op = l.remove();
bp = dynamic_cast<BigThing *>(op);
...
```

Containers

Polymorphic containers

- The `dynamic_cast` operator does the following:

```
dynamic_cast<Type*>(pointer);
// EFFECT: if pointer's actual type is either
// pointer to Type or some pointer to derived
// class of Type, returns a pointer to Type.
// Otherwise, returns NULL;
```

- So, after this cast, we `assert()` that the pointer is valid:

```
Object *op;

BigThing *bp;

op = remove();

bp = dynamic_cast<BigThing *>(op);

assert(bp);
```

Note: This only works for classes which have one or more virtual methods. That's okay, because `BigThing` will always have at least a virtual destructor.

Containers

Polymorphic containers

- Even with this, there is still one problem.

- This is a **container of pointers**, so we need **deep copy** for copy constructor and assignment operator

- The copyList() below just does shallow copy

```
List::List(const List &l) {
  first = NULL;
  copyList(l.first);
}
```
```
void List::copyList(node *list) {
  if (list != NULL) {
    copyList(list->next);
    insert(list->value);
  }
}
```

Object * type
Containers

Polymorphic containers

- Using the previous copyList(), the list we copied will be:

Containers

Polymorphic containers

- Now, if we remove the first item of the `new` list, we delete the first node, and return a pointer to its `Object`.
- The client, after using that `Object`, will delete it.
- Leaving us with this:

To fix this, we need a **deep copy**!

dangling pointer!

Containers

Polymorphic containers

- To fix this, we might be tempted to rewrite the copyList function to create a copy of the Object, as follows:

```
void List::copyList(node *list) {
    if (list != NULL) {
        Object *o;
        copyList(list->next);
        o = new Object(*list->value);
        insert(o);
    }
}
```

A `BigThing` object

- Unfortunately, this won't work, because `Object` does not have a constructor that takes `BigThing` as an argument.

Containers

Polymorphic containers

- The way to fix this is to use something called the "**named constructor idiom**".

    - **named constructor**: A method that (by convention) copies the object, returning a pointer to the "generic" base class.

- The name of this method (again, by convention) is usually "`clone`".

Containers

Polymorphic containers

- Modify the definition of `Object` to include a pure virtual **`clone()`** method:

```
class Object {
 public:
   virtual Object *clone() = 0;
      // EFFECT: copy this, return a pointer to it
   virtual ~Object() { }
};
```

- Declare that method **`clone()`** in `BigThing`, which **also** has a **copy constructor**:

```
class BigThing : public Object {
   ...
 public:
   Object *clone();
   ...
   BigThing(const BigThing &b);
}
```

Containers

Polymorphic containers

- `BigThing::clone()` can then call the correct copy constructor directly, and return a "generic" pointer to it:

```
Object *BigThing::clone() {
  BigThing *bp = new BigThing(*this);
  return bp;   // Legal due to substitution
               // rule
}
```

Containers

Polymorphic containers

- With this, we can finally rewrite copyList to use clone:

```
void List::copyList(node *list){
  if (list != NULL) {
    Object *o;
    copyList(list->next);
    o = list->value->clone();
    insert(o);
  }
}
```

- This gives us a true **deep copy** ☺

Select all the correct statements about polymorphic containers.

- **A.** In the implementation just described, a polymorphic container can hold any type.
- **B.** A polymorphic container could be specialized to only hold subclasses of a class A.
- **C.** A templated container could also hold different objects.
- **D.** A container of pointers could also hold different objects.
